Article submitted on 01 Mar 2017 / accepted on 24 May 2017 / published on 08 Mar 2018

In May 2016, two separate clusters of febrile gastroenteritis caused by *Listeria monocytogenes* were detected by the local health authority in Piedmont, in northern Italy. We carried out epidemiological, microbiological and traceback investigations to identify the source. The people affected were students and staff members from two different schools in two different villages located in the Province of Turin; five of them were hospitalised. The epidemiological investigation identified a cooked beef ham served at the school canteens as the source of the food-borne outbreak. *L. monocytogenes* was isolated from the food, the stools of the hospitalised pupils and the environment of the factory producing the cooked beef ham. All isolates except one were serotype 1/2a, shared an indistinguishable PFGE pattern and were 100% identical by whole genome sequencing (WGS). By combining a classical epidemiological approach with both molecular subtyping and WGS techniques, we were able to identify and confirm a *Listeria* gastroenteritis outbreak associated with consumption of sliced cold beef ham.

Introduction

Listeria monocytogenes is a ubiquitous Gram-positive food-borne pathogen that causes listeriosis both in humans and in several animal species. In some groups (people with weakened immune systems, older adults, newborns, pregnant women and their unborn babies), the disease can be an important cause of life-threatening septicaemia and meningoencephalitis [1]. Food-borne transmission of *L. monocytogenes* can also cause a self-limited acute febrile gastroenteritis, primarily reported among healthy people.

L. monocytogenes is widely distributed in natural environments and has been isolated from soil, decaying vegetation, stream water, sewage, urban environments and human and animal faeces [2]. Its ubiquity and ability to adapt and to survive under environmentally stressed conditions make it challenging to control and eradicate *L. monocytogenes* in food-processing environments and constitute a concern for the food industry [2]. The role of *L. monocytogenes* in food-borne outbreaks has been clearly recognised in the last decades [3-6]. Since 1993, listeriosis has been a reportable disease in Italy.

Outbreak description

On 5 May 2016, five children from School A, an institution that includes two scholastic levels, a nursery with pupils aged 3–6 years and a primary school with pupils aged 6–10, and located in village A, a municipality of the province of Turin, were taken to the paediatric emergency room for symptoms of acute febrile gastroenteritis. On the same day, 26 of 162 (16%) pupils from the nursery and 25 of 400 (6%) pupils from the primary school returned home early (some of them before lunch time) because of fever, vomiting and abdominal pain. A report of a suspected food-borne outbreak was sent by the paediatric emergency room to the local health authority. In the following 3 days, additional pupils and staff from School A became ill including one hospitalised. On 6 May, the inspectors from the local health authority went to the mass catering food service (Caterer A) that provides meals to School A and collected retention samples (i.e. representative samples of the full meal stored by the mass catering food service) from the meals served on 3, 4 and 5 May 2016.

FIGURE 1

Epidemic curve of gastrointestinal illness in two schools, *Listeria monocytogenes* outbreak, Italy, May 2016 (n = 217)

The plot shows a classical point-source epidemic. Bars indicate probable cases by date of onset.

From 25 to 29 May 2016, 20 days after this first cluster was identified, children from School B, located in village B in the same Province, reported gastrointestinal symptoms similar to those in the first cluster. Once again, the local health authority inspectors collected retention samples from the mass catering food service (Caterer B, different from the previous one) that provided meals to School B.

We present the results of epidemiological, microbiological and traceback investigations for source attribution.

Methods

Case finding and hypothesis generation

An investigation team was created involving personnel from the local health authority, the hospital microbiology laboratory of Turin (Città della Salute) and the regional branch of the Istituto Zooprofilattico Sperimentale (IZS) in Turin as coordinating unit, dealing with both epidemiology and food analysis.

A standardised trawling questionnaire for gastrointestinal illness including questions on clinical symptoms, canteen attendance and foods eaten, was distributed by the local health authority to all the pupils' parents and to staff of Schools A and school B. Administration of the questionnaire was postponed 20 days for the cluster associated with School B because of school holidays. At the IZS, questionnaire data were entered

in an ad hoc database and analysed using Stata 14.1 [7] software.

Foods and environmental samples were submitted to the IZS laboratories for pathogen detection and quantification, and faecal samples were sent to the microbiology laboratory of the local hospital.

Case definition

We initially defined a probable case as an attendee (pupils or staff) of School A or School B presenting with at least two of the following symptoms: headache, nausea, vomiting, diarrhoea, abdominal pain, temperature above 38°C and an onset date starting from the day before the peak of the associated cluster. This definition served as the basis to build the epidemic curve for both clusters of the outbreak.

Individuals who reported symptom onset 2 days before the peak of the associated cluster were excluded from the case definition to favour specificity over sensitivity, and because information on foods eaten at this time was not available.

After a preliminary cohort analysis in School A, and to further increase specificity, we amended the case definition for the first cluster and defined a probable case as an attendee of School A presenting with at least three of the above-mentioned symptoms. This narrower operational case definition was not applied to the second cluster as there could have been a recall bias on the number of symptoms because of the time lag between the illness and the interviews.

We also used a final case definition for a confirmed case: an attendee of School A or School B presenting clinical symptoms and whose diagnostic test on stool samples confirmed the presence of *L. monocytogenes*.

Cohort study and statistical analysis

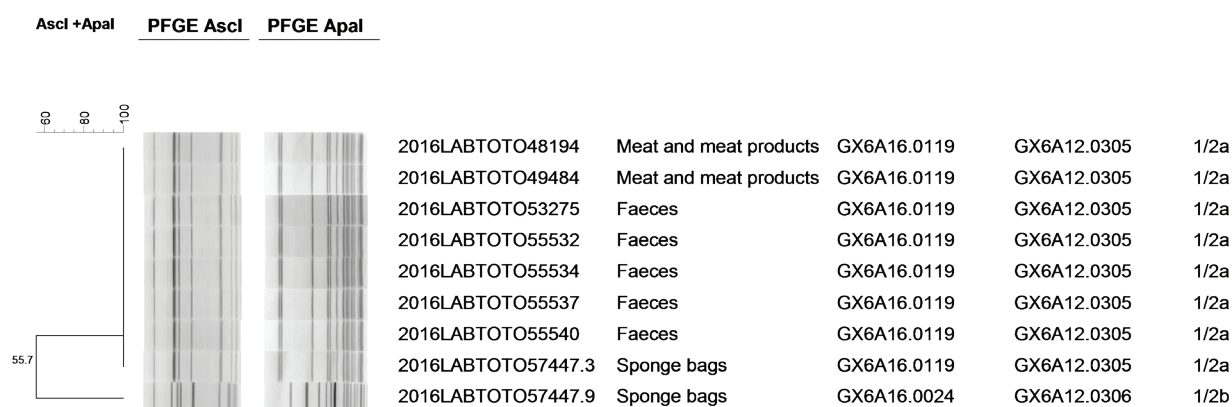

We conducted a retrospective cohort study and calculated the attack rate (AR) and the relative risk (RR) for each food item. Confidence interval was set at 95% (95% CI).

For the first cluster, statistical analysis was performed both on the overall School A dataset and at the nursery and primary school level, used as a proxy for age. Only exposure data regarding 3 and 4 May were taken into account as the epidemic peak occurred on 5 May 2016 and it seemed unlikely that the meal served on that date, or later, could be the source of infection.

For the second cluster, the same exclusion criteria were applied and the data analysis referred to the meals consumed on 25 and 26 May.

FIGURE 2

Dendrogram showing genetic similarity and genomic clusters of *Listeria monocytogenes* strains isolated from sliced beef ham, stools and environmental samples, Italy, May 2016 (n = 9)

Clusters are indicated on the side of the figure. The identification numbers of isolates, origin of the samples, Ascl and Apal profiles and serotypes are listed in the columns.

Microbiological investigation and traceback

Retention samples, other food samples and environmental samples

Retention samples were sent to the food control laboratory of the IZS for quantification of *Bacillus cereus*, beta-glucuronidase-positive *Escherichia coli*, *Clostridium perfringens*, *Enterobacteriaceae*, coagulase-positive staphylococci, *Listeria monocytogenes* and sulfite-reducing anaerobic bacteria by routine methods. Samples were also tested for *B. cereus* diarrhoeal and emetic toxins, norovirus, *Salmonella* spp., Shiga toxin-producing *E. coli*, and staphylococcal enterotoxins.

Regarding the first cluster and following preliminary analysis of the data, a specific food item was suspected as the source of the outbreak. Hence the local health authority was requested to trace-back the retailer and the producer to collect additional samples of the suspected food. Therefore, two weeks after the peak, one more food sample, an unopened package from a different batch, was collected from the producer (a cured meat factory) who had supplied the suspected food to the mass catering food service.

Regarding the second cluster, only retention samples from the meal served on 26 May 2016 were available at the mass catering food service, and an unopened package of the suspected food item from the same batch as the one served was retrieved from the producer. The same producer supplied the two mass catering food services involved in the two clusters. Environmental samples were collected pre-moistened sampling cellulose sponge bags (Solar-Cult, Solar Biologicals Inc, Vancouver, Canada) from surfaces that were not in contact with food at the mass catering food service that

served School B and at the producer who had supplied food to both mass catering services.

Stool samples

Stool specimens were collected from the five hospitalised children (four from the first cluster and one from second cluster) and cultured using specific culture media for pathogenic bacteria (*B. cereus*, *Campylobacter* spp., *L. monocytogenes*, *Salmonella* spp., Shiga toxin-producing *E. coli*, *Shigella* spp., *Staphylococcus aureus*, and *Yersinia enterocolitica*). Characteristic colonies were only on *Listeria* medium (PalcamAgar, Liofilchem, Italy). *Listeria* strains were identified by MALDI-TOF technology.

Identification of the *Listeria monocytogenes* strains

All *L. monocytogenes* strains isolated from stool, food and environmental samples were identified according to the ISO 11290 method using the Vitek MS system (bioMérieux, Marcy l'Etoile, France) and serotyped based on agglutination reactions with antisera for *L. monocytogenes* (Denka Seiken Co., Tokyo, Japan).

Pulsed-field gel electrophoresis (PFGE) was performed by the National Reference Laboratory for *L. monocytogenes* in Teramo, according to the United States Centres for Disease Control and Prevention PulseNet protocol [8], and analysed with Applied Maths BioNumerics software package (Version 7.5, Applied Maths, Saint-Martins-Latem, Belgium).

Whole genome sequencing

Whole Genome Sequencing (WGS) of the DNA extracted from *L. monocytogenes* isolates was performed on the MiSeq platform (Illumina, San Diego, United States),

FIGURE 3

Single-nucleotide polymorphism analysis of *Listeria monocytogenes* isolates, Italy, May 2016 (n = 9)

The maximum likelihood tree done with the CSI Phylogeny 1.2 tool highlights two distinct clusters, one that includes eight ST11 isolates and one that includes the ST5 environmental isolate and the reference strain “*L. monoreference*” (GenBank accession number: AL591824.1).

using paired-end libraries which were prepared by following the Nextera XT DNA Library Preparation Kit (Illumina, San Diego, United States), with 200-bp read length. The reads were first subjected to FastQC Read Quality reports (Galaxy Version 0.65, accessed via the Galaxy public server at <https://usegalaxy.org>) [9] to provide the quality control checks on raw sequence data. We used Assembler 1.2 (accessed via Technical University of Denmark, DTU Center; <https://cge.cbs.dtu.dk/services/Assembler/>) to assemble genomes [10]. All samples were processed for multilocus sequence typing (MLST) with MLST 1.8 (accessed via <https://cge.cbs.dtu.dk/services/MLST/>) [10]. A phylogenetic comparison was made with CSI Phylogeny 1.2 (accessed via <https://cge.cbs.dtu.dk/services/CSIPhylogeny/>) [11]. The single-nucleotide polymorphism (SNP)-typing phylogenetic method was used because of its high discriminatory power that allows distinguishing very closely related isolates to a degree not achievable by other typing methods [12]. SNP was performed with the following parameters: 10 × minimum depth at SNP position, 10% minimum relative depth at SNP position, 100 bp minimum distance between SNPs, 20 for minimum SNP quality, 20 for minimum read mapping quality, 1.98 minimum Z-score for each SNP, and including *L. monocytogenes* (GenBank accession number: AL591824.1) as reference.

Results

Epidemiological investigations

The epidemic curve of the whole outbreak is shown in Figure 1. For each cluster, the pattern was compatible with a point-source epidemic.

In the investigation of the first cluster, 484 completed questionnaires (response rate: 91.7%) were collected and used to build the cohort study. Symptoms were reported by 174 persons; 162 of 484 (33.7%) matched the probable case definition, while 11 people were excluded from the analysis. Reported symptoms among the 162 were: abdominal pain (n = 122; 75%),

fever (n = 110; 68%), headache (n = 102; 63%), nausea (n = 85; 52%), diarrhoea (n = 79; 49%) and vomiting (n = 47; 29%). Two probable cases were staff members. All five probable cases who went to the hospital were afterwards confirmed.

Eight retention samples were analysed. As the microbiological analysis did not give any positive results, the output of the first cluster cohort analysis were used to hypothesise the most likely source of infection. ARs and RRs (Table 1) showed a positive association between consumption of a ‘beef ham’ (sliced cold beef meat, cured-cooked and dressed with oil and lemon) and the disease (RR=2.23; 95% CI: 1.30–3.84). The association between the beef ham and the disease was still significant when stratifying the analysis by school level (nursery vs primary school) (Table 1). Moreover, the strength of the association further increased by using the narrower operational case definition (RR=3.5; 95% CI: 1.5–8.3).

A significant RR > 1 was found between the disease and the consumption of halibut (RR=1.48; 95% CI: 1.02–2.14) for the initial case definition. However, this association disappeared after stratification by school (Table 1). When using the narrower case definition, halibut consumption again did not have a statistically significant association with the cases (RR=1.18; 95% CI: 0.76–1.84), hence we considered it a chance finding and did not proceed to investigate it further.

In the investigation of the second cluster, 382 questionnaires were collected (response rate: 86.8%), although the questionnaires were administered with a delay of 20 days because of school holidays. Of these, 30 were excluded because data were not complete, and 352 were used for the cohort study analysis. Of those 352, 43 (12%) matched the probable case definition, with a peak of the outbreak on 27 May 2016 (Figure 1). The frequency of symptoms among those 43 was similar to the first cluster: abdominal pain (n = 34) headache (n = 25) fever (n = 23), nausea (n = 22), diarrhoea (n = 17) and vomiting (n = 13). We did not find any statistically significant associations, although the beef ham was the food item with the highest RR (RR=1.4; 95% CI: 0.62–3.15; total responses: 268; 34 cases among 215 exposed and six cases among 53 unexposed).

Microbiological investigations

Based on the results of the epidemiological analysis of the first cluster, a microbiological analysis was carried on both the retention sample and on the additional unopened package of the beef ham from the same batch as the one served in school A (batch no. 127529). Moreover, a retention sample and an unopened package belonging to the same batch as the one served in School B (batch no. 130578) from the second cluster were analysed, along with stools specimens from both the clusters and environmental samples from the shared producer (Table 2).

1 and 2	1	Environmental sample (cutter machine)	Producer	Presence	ND	1/2a	GX6A16.0119 / GX6A12.0305	ST11
1 and 2	1	Environmental sample (fridge handle)	Producer	Presence	ND	1/2b	GX6A16.0024 / GX6A12.0306	ST5

cfu: colony-forming units; MLST: multilocus sequence type; ND: not done; PFGE: pulsed-field gel electrophoresis.

As a result, nine of 23 samples tested positive for *L. monocytogenes*. These were five stool samples (four from the first cluster and one from the second cluster), two food samples (one unopened package from a different batch obtained during the investigation of the first cluster and one retention sample from the second cluster, both with a count exceeding 15,000 colony-forming units (cfu)/g) and two environmental samples from the incriminated producer's premise (one from the cutter machine and one from the fridge handle).

Identification of the *Listeria* strain

Both the unopened batch (no. 127529) of beef ham collected during the investigation of the first cluster and the beef ham from the retention samples collected during the investigation of the second cluster tested positive for *L. monocytogenes*, with >15,000 cfu/g and 15,000 cfu/g, respectively. In addition, seven *L. monocytogenes* isolates were obtained from the stool specimens from five children and from two environmental samples from the producer. Agglutination reactions assigned eight isolates to serotype 1/2a, while the remaining one (from the producer) was serotype 1/2b. In addition, all serotype 1/2a isolates showed indistinguishable PFGE pattern whereas the serotype

1/2b strain showed a different PFGE profile (Figure 2 and Table 2).

Whole genome sequencing data analysis

In silico MLST showed that all serotype 1/2a isolates belonged to ST11 and the 1/2b isolate was ST5 (Table 2). The maximum likelihood tree obtained through the SNPs analysis showed two distinct clusters. The first cluster included eight ST11 isolates and the second cluster included the reference genome and the environmental ST5 isolate (Figure 3).

The maximum likelihood tree done with the CSI Phylogeny 1.2 tool highlights two distinct clusters, one that includes eight ST11 isolates and one that includes the ST5 environmental isolate and the reference strain "L. monoreference" (GenBank accession number: AL591824.1).

Discussion

By combining an epidemiological approach and molecular typing including WGS techniques, we were able to identify and confirm a *Listeria* outbreak associated with the consumption of one food item, sliced cold beef ham.

The outbreak consisted of two school-associated clusters of non-invasive listeriosis cases linked to one *L. monocytogenes* strain. Cases experienced mostly abdominal pain, fever, headache and nausea. Gastrointestinal symptoms occurred rapidly after consumption of the incriminated meals, probably because a large dose of *L. monocytogenes* was ingested. A short incubation period for *L. monocytogenes*-associated gastroenteritis varying from 6 to 240 hours has already been reported elsewhere [13].

This outbreak was characterised by a high level of contamination of the suspected food. Unfortunately, it was not possible to determinate the exact number of *L. monocytogenes* in the beef ham sampled during the investigation of the first cluster because the laboratory in charge of official control had not expected a very high level of contamination and therefore only performed the dilutions needed in compliance with the Commission Regulation (EC) no. 2073/2005 to determine the threshold of *L. monocytogenes* <100 cfu/g. It was not possible to repeat the analysis because it is mandatory to discard the samples after microbiological investigation. Isolation of a matching strain from the cutter machine suggests that the food contamination probably occurred in the production plant.

Another remarkable feature of the outbreak was the quite long persistence of the contamination. Norton et al. showed that specific *L. monocytogenes* ribotypes persisted over time in the environments of two of three processing plants for smoked fish [14]. Similar findings have been reported by a variety of groups that showed persistence of specific *L. monocytogenes* subtypes in different processing plants for smoked fish, poultry, meat or dairy [15-17]. In our investigation, the time span was 20 days from the first isolation of *Listeria* in the beef ham (unfortunately the date of production of the contaminated batch was not available) and the isolation from the environment of the cured meat factory where the beef ham was produced. This further confirms that *L. monocytogenes* can persist in the environment.

Among the 13 known serotypes of *L. monocytogenes*, the ones most frequently associated with human listeriosis are 1/2a, 1/2b and 4b, representing more than 95% of the infections. Our results are consistent with previous reports suggesting that serotype 1/2a is predominant in *L. monocytogenes*-associated gastroenteritis outbreaks [18], whereas serotype 4b was the most frequent up to 2010 and 4b is still the most reported serotype in invasive listeriosis outbreaks [19,20].

Although *L. monocytogenes* was not found in the retention sample of the first cluster, the epidemiological investigation was helpful in identifying a strong association between the consumption of beef ham and the disease. This association triggered the targeting and retrieval of a specific food for further microbiological analysis. A possible but weak association with another

food, halibut, was seen in a first analysis based on the initial case definition, but not in stratified analysis. When using the narrowed case definition, it was considered a chance finding and no traceback was performed for halibut. Findings from the cohort study of the second cluster, although not statistically significant, were consistent and supported the same hypothesis. As shown by the inconclusive results from the epidemiological investigation of the second cluster, a stand-alone epidemiological approach may suffer from problems associated with the data collection or from a small sample size when the affected individuals come from a small community. In the second cluster, distribution and collection of questionnaires had to be carried out with some delay (20 days after the peak of the outbreak) leading to incomplete answers and probably recall problems. Consequently, there was the potential for non-differential misclassification of the exposure. That, combined with the small sample size, may explain our failure to obtain a statistically significant association.

However, microbiological, molecular typing and WGS data helped confirm the link between the clusters that appeared to be independent based on the spatial distance (two different municipalities), the 20-day interval between them and the different catering suppliers. Historically, food-borne disease outbreaks of local scale, often linked to a single restaurant or social event, are caused by pathogens other than *Listeria* (e.g. *Salmonella*), even if *Listeria* have also been reported in connection with local outbreaks [21]. This is one example of a short *Listeria* outbreak that can also be responsible for scattered epidemics. Today, outbreaks often involve food products that are centrally produced and widely distributed geographically. In our case, two different mass catering food suppliers that served a number of schools scattered over many municipalities were supplied by a unique cured meat factory.

The problems in identifying the epidemiological links were successfully addressed through an integrated approach including questionnaire-based studies, trace-back investigations and biomolecular techniques. In the current study, the use of WGS made it possible to link human cases that occurred over a period of 20 days, brought about the understanding that there was in fact a single continuous outbreak source, and established links between two different mass catering food suppliers and one producer.

The correlation between food, stool and environmental specimens found in WGS, MLST and the phylogenetic analysis based on SNPs provided sufficient evidence for the local authorities to act accordingly and recall the contaminated food to prevent more outbreak-related cases. The authorities were also advised to monitor the follow-up of people exposed to the incriminated beef ham as it has been reported that severe listeriosis can have a long incubation period.

The output of the analysis from the first cluster highlighted a heavier impact in 6–10 year-old pupils than in younger ones, associated with a modification of effect between the exposure to *L. monocytogenes* and the age of the children. This may be explained by larger servings offered to the older pupils who probably experienced the highest exposure.

Conclusion

The current study stresses the importance of an integrated approach when dealing with public health issues and suggests the usefulness of diagnostic techniques that enable clustering of isolates from different episodes.

Acknowledgements

The authors gratefully acknowledge the Prevention Operator/Technician (TPALL) and the veterinary officers involved in tracing back the food and in performing the environmental samplings and Dr Marion M Simmons for her valuable suggestions in improving the English spelling of the text.

Conflict of interest

None declared.

Authors' contributions

Cristiana Maurella and Giuseppe Ru analysed the epidemiological data and wrote the article. Margherita Croce, Maria Franca Dupont and Stefano Stanzone administered and collected the interviews. Valeria D'Errico, Alessandro Marra, Ubaldo Natangelo entered and managed the epidemiological data. Silvia Gallina, Daniela Adriano and Fabio Zuccon carried out the laboratory analyses on food and environmental samples. Alberto Bellio, Angelo Romano, and Lucia Decastelli typified bacteria isolates from faecal, food and environmental samples. Teresa Zaccaria collected and analysed the faecal samples. Francesco Pomilio performed the strain identification and critically revised the article. Maria Ines Crescio and Laura Chiavacci internally revised the paper. Maria Caramelli and Daniela Manila Bianchi coordinated the communication between the involved public health authorities. All the authors contributed to the discussion of the article.
